# $\epsilon$ -Lexicase selection: a probabilistic and multi-objective analysis of lexicase selection in continuous domains

March 15, 2017

#### Abstract

Lexicase selection is a parent selection method that considers test cases separately, rather than in aggregate, when performing parent selection. As opposed to previous work that has demonstrated the ability of lexicase selection to solve difficult problems, the goal of this paper is to develop the theoretical underpinnings that explain its performance. To this end, we derive an analytical formula that gives the expected probabilities of selection under lexicase selection, given a population and its behavior. In addition, we expand upon the relation of lexicase selection to many-objective optimization methods to show the effect of lexicase, which is to select individuals on the boundaries of Pareto fronts in high-dimensional space. We show analytically why lexicase selection performs more poorly for certain sizes of population and training cases, and why it has been shown to perform more poorly in continuous error spaces. To address this last concern, we introduce  $\epsilon$ -lexicase selection, which modifies the pass condition defined in lexicase selection to allow near-elite individuals to pass cases, thereby improving selection performance. We show that  $\epsilon$ -lexicase outperforms several diversity-maintenance strategies for problems from three continuous-valued domains: regression, dynamical systems, and program synthesis.

# 1 Introduction

Evolutionary computation (EC) traditionally assigns scalar fitness values to candidate solutions to determine how to guide search. In the case of genetic programming (GP), this fitness value attempts to capture how closely, on average, the behavior of the candidate programs match the desired behavior. Take for example the task of symbolic regression, in which we attempt to find a model using a set of training examples, i.e. cases or tests. A typical fitness measure is the mean squared error (MSE), which averages the squared differences between the model's outputs and the target output. Given that individual comparisons of each program's output to y is reduced to a single value, the relationship of  $\hat{y}$  to y can only be represented crudely by the fitness value. The fitness score thereby restricts the information conveyed to the search process about candidate programs relative to the description of their behavior available in the raw comparisons of the output to the target (i.e., the squared error), information which could help guide the search [9]. This observation has led to increased interest in the development of methods that can leverage the program outputs, i.e. semantics, directly to drive search more effectively [15].

In addition to reducing information, averaging test performance assumes all tests are equally informative, leading to the potential loss of individuals who perform poorly on average even if they are the best on a test case that is difficult for most of the population to solve. This is particularly relevant for problems that require different modes of behavior to produce an adequate solution to the problem [14]. The underlying assumption of GP in this regard is that selection pressure should be applied evenly with respect to test cases, ignoring the fact that cases that comprise the problem are unlikely to be uniformly difficult. As a result, the search is likely to benefit if it can take into account the difficulty of specific cases by recognizing individuals that perform well on harder parts of the problem. Underlying this last point is the assumption that GP solves problems by identifying, propagating and recombining partial solutions (i.e. building blocks) to the task at hand(cite schema Poli). As a result, a program that performs well on unique subsets of the problem may imply a partial solution to our task.

Several methods have been proposed to reward individuals with uniquely good test performance, such as implicit fitness sharing (IFS) [13], historically assessed hardness [7], and co-solvability [8], all of which assign

greater weight to fitness cases that are judged to be more difficult in view of the population performance. Perhaps the most effective parent selection method designed to account for case hardnedss is lexicase selection [6, 14]. In particular, "global pool, uniform random sequence, elitist lexicase selection" [14], which we refer to simply as lexicase selection, has outperformed other similarly-motivated methods in recent studies [5, 12]. Despite these gains, it fails to produce such benefits when applied to continuous symbolic regression problems, due to its method of selecting individuals based on test case elitism. For this reason we recently proposed [10] modulating the case pass conditions in lexicase selection using an automatically defined  $\epsilon$  threshold, by allows the benefits of lexicase selection to be achieved in continuous domains.

To date, the work to analyze lexicase selection and  $\epsilon$ -lexicase selection has mostly been empirical studies, rather than algorithmic analysis. Previous work has not explicitly described the probabilities of selection under lexicase selection or how lexicase selection relates to multi-objective methods. The foremost purpose of this paper is to lay the groundwork for describing how lexicase selection and  $\epsilon$ -lexicase selection pressure selection compared to traditional approaches. With this in mind, in §5 we derive an equation that describes the expected probability of selection for individuals in a given population based on their behavior on the training cases, for all variants of lexicase selection. Then in §6, we analyze lexicase and  $\epsilon$  lexicase selection from a multi-objective viewpoint, in which we imagine each training case to be an objective. We prove that individuals selected by lexicase selection exist at the boundaries of the Pareto front in the high-dimensional space defined by the program error vectors. We show via an illustrative example population in §7 how the probabilities of selection differ under tournament, lexicase, and  $\epsilon$ -lexicase selection.

We propose two new methods for defining pass conditions in  $\epsilon$ -lexicase which are shown to improve the method compared to the original implementation. A final set of experiments compares variants of  $\epsilon$ -lexicase selection to several existing selection techniques on a set of real world benchmark problems. The results show that ability of  $\epsilon$ -lexicase selection to improve the predictive accuracy of models on these problems. We examine in detail the diversity of programs during these runs, as well as the number of cases used in selection events to validate our hypothesis that  $\epsilon$ -lexicase selection allows for more cases to be used in selecting individuals compared to lexicase selection.

## 2 Preliminaries

In symbolic regression, we attempt to find a model  $\hat{y}(\mathbf{x}) : \mathbb{R}^d \to \mathbb{R}$  using a set of training examples  $\mathcal{T} = \{t_i = (y_i, \mathbf{x}_i)\}_{i=1}^T$ , where  $\mathbf{x}$  is a d-dimensional vector of variables i.e. features, and y is the desired output. A typical fitness measure is the mean squared error (MSE), which averages the squared differences between  $\hat{y}$  and y.

We denote the population of N programs as  $\mathcal{N} = \{n_i\}_{i=1}^N$  and the paired examples on which they learn as  $\mathcal{T} = \{t_i = (y_i, \mathbf{x}_i)\}_{i=1}^T$ . We refer to elements of  $\mathcal{T}$  as "cases". A program  $n \in \mathcal{N}$  produces an approximation  $\hat{y}_t(n, \mathbf{x}_t) : \mathbb{R}^d \to \mathbb{R}$  when evaluated on case t. We refer to the squared error of this approximation as  $e_t(n) = (y_t - \hat{y}_t(n))^2$ , and denote the errors produced by a program on all of the training cases as the program's semantics. We use  $\mathbf{e_t} \in \mathbb{R}^N$  to refer to the set of all errors in the population on training case t.

 $\mathcal{T} = \{(y_t, \mathbf{x}_t)\}_{t=1}^N$ , using e.g. the mean absolute error (MAE), which is quantified for individual program  $i \in P$  as:

$$MSE(\mathcal{T}) = \frac{1}{N} \sum_{t \in \mathcal{T}} |y_t - \hat{y}_t(\mathbf{x}_t)|$$
 (1)

where  $\mathbf{x} \in \mathbb{R}^D$  represents the variables or features, the target output is y and  $\hat{y}(i, \mathbf{x})$  is the program's output. As a result of the aggregation of the absolute error vector  $e(i) = |y - \hat{y}(i, \mathbf{x})|$  in Eq. (1), the relationship of  $\hat{y}$  to y is represented crudely when choosing models to propagate.

### 3 Lexicase Selection

Lexicase selection is a parent selection technique based on lexicographic ordering of test (i.e. fitness) cases. The lexicase selection algorithm for a single selection event is presented below:

#### Algorithm 1: Lexicase Selection

```
GetParent(\mathcal{N}, \mathcal{T}):
    T' \leftarrow \mathcal{T}
                                                                training cases
    S \leftarrow \mathcal{N}
                                                                initial selection pool is the population
    while |T'| > 0 and |\mathcal{S}| > 1:
                                                                main loop
       \texttt{case} \leftarrow random \ choice \ from \ \mathcal{T}'
                                                                    consider a random case
       elite \leftarrow best fitness in S on case
                                                                    determine elite fitness
       \mathcal{S} \leftarrow n \in \mathcal{S} \text{ if } \text{fitness}(n) = \texttt{elite}
                                                                    reduce selection pool to elites
       \mathcal{T}' \leftarrow \mathcal{T}' - \mathsf{case}
                                                                    reduce remaining cases
    return random choice from S
                                                                return parent
```

Algorithm 1 is very simple to implement because it consists of just a few steps: 1) choosing a case, 2) filtering the selection pool based on that case, and 3) repeating until the cases are exhausted or the selection pool is reduced to one individual. If the selection pool is not reduced by the time each case has been considered, an individual is chosen randomly from the remaining pool, S.

Under lexicase selection, cases in  $\mathcal{T}$  can be thought of as filters that reduce the selection pool to the individuals in the pool that are best on that case. It's important to note that each parent selection event constructs a new path through these filters. The filtering strength of the case is affected by two main factors: 1) its difficulty as defined by the number of individuals that pass it, and 2) its order in the selection event, which varies from selection to selection. Regarding 1), consider two extreme examples: if a case is passed by the whole population, then it will perform no filtering, resulting in no selection pressure; if a case is passed by a single individual, that individual will be selected every time the case is considered for a selection pool containing the individual that passes it. This mechanism allows selective pressure to continually shift to individuals that are elite on cases that are not widely solved in  $\mathcal{N}$ . Because of 2), cases appear in various orderings during selection, resulting in selective pressure for individuals that solve difficult subsets of cases. Lexicase selection thereby accounts not only for the difficulty of individual cases but the difficulty of solving arbitrarily-sized subsets of cases. This selection pressure leads to the preservation of high behavioral diversity during evolution [6, 10].

# 4 $\epsilon$ -Lexicase Selection

Lexicase selection has been shown to be effective in discrete error spaces, both for multi-modal problems [14] and for problems for which every case must be solved exactly to be considered a solution [6]. In continuous error spaces, however, the requirement for individuals to be elite to pass a case during selection turns out to be overly stringent [10].

$$\epsilon_t = \text{median}(\mathbf{e_t} - \text{median}(\mathbf{e_t}))$$
 (2)

We study three implementations of  $\epsilon$ -lexicase selection in this paper: static, which is the version used in the conference paper [?], semi-dynamic, in which the error is defined relative to the pool, and dynamic, in which both the error and  $\epsilon$  are defined relative to the current selection pool.

### Static $\epsilon$ -Lexicase Selection

```
{\tt GetParent}(\mathcal{N},\mathcal{T}) :
    T' \leftarrow \mathcal{T}
                                                                                                  training cases
    S \leftarrow \mathcal{N}
                                                                                                 initial selection pool is the population
     \epsilon \leftarrow MAD(\text{fitness}(\mathcal{N})) \text{ for } t \in \mathcal{T}
                                                                                                 get \epsilon for each case
    fitness(n) \leftarrow \mathbb{I}(e_t(n) \leq e_t^*(n) + \epsilon_t) for t \in \mathcal{T} and n \in \mathcal{N}
                                                                                                 convert fitness using within-\epsilon pass condition
     while |T'| > 0 and |S| > 1:
        \mathtt{case} \leftarrow \mathrm{random} \ \mathrm{choice} \ \mathrm{from} \ \mathcal{T}'
                                                                                                     consider a random case
        elite \leftarrow best fitness in S on case
                                                                                                     determine elite fitness
        S \leftarrow n \in S \text{ if } fitness(n) \leq elite
                                                                                                     reduce selection pool to elites
        \mathcal{T}' \leftarrow \mathcal{T}' - \mathtt{case}
                                                                                                     reduce remaining cases
     return random choice from S
                                                                                                  return parent
```

Static  $\epsilon$ -lexicase selection can be viewed as a preprocessing step added to lexicase selection in which the program errors are converted to pass/fail based on an  $\epsilon$  threshold defined relative to  $\mathbf{e}_t^*$ , the best error in  $\mathcal{N}$  on t.

#### Semi-dynamic $\epsilon$ -Lexicase Selection

```
{\tt GetParent}(\mathcal{N},\mathcal{T}):
    T' \leftarrow \mathcal{T}
                                                                         training cases
    S \leftarrow \mathcal{N}
                                                                         initial selection pool is the population
     \epsilon \leftarrow MAD(\text{fitness}(\mathcal{N})) \text{ for } t \in \mathcal{T}
                                                                         get \epsilon for each case
     while |T'| > 0 and |\mathcal{S}| > 1:
                                                                          main loop
        \mathtt{case} \leftarrow \mathrm{random} \ \mathrm{choice} \ \mathrm{from} \ \mathcal{T}'
                                                                             consider a random case
        \texttt{elite} \leftarrow \text{best fitness in } \mathcal{S} \text{ on case}
                                                                             determine elite fitness
        S \leftarrow n \in S if fitness(n) \leq elite + \epsilon_{case}
                                                                             reduce selection pool to elites
        \mathcal{T}' \leftarrow \mathcal{T}'- case
                                                                             reduce remaining cases
    return random choice from S
                                                                         return parent
                                                                      Dynamic \epsilon-Lexicase Selection
GetParent(\mathcal{N}, \mathcal{T}):
    T' \leftarrow \mathcal{T}
                                                                         training cases
    S \leftarrow \mathcal{N}
                                                                         initial selection pool is the population
     while |T'| > 0 and |\mathcal{S}| > 1:
                                                                          main loop
        \texttt{case} \leftarrow \mathrm{random} \ \mathrm{choice} \ \mathrm{from} \ \mathcal{T}'
                                                                             consider a random case
        elite \leftarrow best fitness in S on case
                                                                             determine elite fitness
        \epsilon \leftarrow MAD(\text{fitness}(\mathcal{S})) \text{ on case}
                                                                             determine \epsilon for this case
        S \leftarrow n \in S \text{ if } fitness(n) \leq elite + \epsilon_{case}
                                                                             reduce selection pool to elites
        \mathcal{T}' \leftarrow \mathcal{T}' - \mathtt{case}
                                                                             reduce remaining cases
     return random choice from S
                                                                         return parent
```

# 5 Expected Probabilities of Selection

What is the probability of an individual being selected, given its performance in a given population on a set of training cases?

To put it into words, the probability of n being selected is the probability that a case n passes (a member of  $\mathcal{K}_n$ ) is selected and:

- 1. no more cases remain and n is selected among the set of individuals that pass the selected case; or
- 2. n is the only individual that passes the case; or
- 3. n is selected via the selection of another case that n passes (repeating the process).

Formally, let  $P_{sel}(n|\mathcal{N}, \mathcal{T})$  be the probability of n being selected in a population  $\mathcal{N}$  with training cases  $\mathcal{T}$ . Let  $\mathcal{K}_n(\mathcal{T}, \mathcal{N}) = \{k_i\}_{i=1}^K \subseteq \mathcal{T}$  be the training cases from  $\mathcal{T}$  for which individual n is elite among  $\mathcal{N}$ . We will use  $\mathcal{K}_n$  for brevity. Then the probability of selection under lexicase can be represented as a piece-wise recursive function:

$$P_{sel}(n|\mathcal{N},\mathcal{T}) = \begin{cases} 1 & : & |\mathcal{T}| > 0, |\mathcal{N}| = 1; \\ \frac{1}{|\mathcal{T}|} \sum_{k_s \in K_n} P_{sel} \left( n|\mathcal{N}(m|k_s \in K_m), \mathcal{T}(t|t \neq k_s) \right) & : & \text{otherwise} \end{cases}$$

$$(3)$$

The first two elements of  $P_{sel}$  follow from the lexicase algorithm: if there is one individual in  $\mathcal{N}$ , then it is selected; otherwise if there no more cases in in  $\mathcal{T}$ , then n has a probability of selection split among the individuals in  $\mathcal{N}$ , i.e.,  $1/|\mathcal{N}|$ . If neither of these conditions are met, the remaining probability of selection is  $1/|\mathcal{T}|$  times the summation of  $P_{sel}$  over n's elite cases. Each case for which n is elite among the current pool (represented by  $k_s \in K_n$ ) has a probability of  $1/|\mathcal{T}|$  of being selected. For each potential selection  $k_s$ , the probability of n being selected as a result of this case being chosen is dependent on the number of individuals that are also elite on these cases, represented by  $\mathcal{N}(m|k_s \in K_m(\mathcal{T}))$ , and the cases that are left to be traversed, represented by  $\mathcal{T}(t|t \neq k_s)$ .

Eqn. 3 also describes the probability of selection under  $\epsilon$ -lexicase selection, with the condition that *elitism* on a case is defined as being within  $\epsilon$  of the best error on that case, where the best error is defined among the whole population (statically) or among the current selection pool (semi-dynamic and dynamic). The definition of  $\epsilon$  differs according to whether static, semi-dynamic, or dynamic lexicase are being used as well.

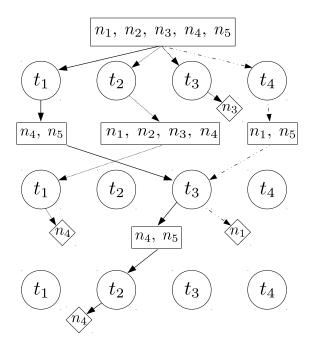

Figure 1: A graphical representation of 3 example parent selections using lexicase selection on the population in Table 1. The bold, dashed and dot-dashed lines indicate different selection paths through the test cases in circles. The boxes indicate the selection pool at each step in the process.

Intuitions according to edge cases According to Eqn. 3, when fitness values across the population are unique, selection probability is  $\frac{1}{|\mathcal{T}|} \sum_{k_s \in \mathcal{K}_n(\mathcal{T})} 1 = \frac{|\mathcal{K}_n|}{|\mathcal{T}|} \, \forall n$ , since filtering the population according to any case for which n is elite will result in n being selected. Conversely, if the population semantics are completely homogeneous such that every individual is elite on every case, the selection will be uniformly random, giving the selection probability  $\frac{1}{N} \, \forall n$ . In fact, this holds true for individual cases: a case t will have no impact on the probability of selection of n if  $t \notin K_n \, \forall n, t \in \mathcal{N}, \mathcal{T}$ . This is clear when viewed from the lexicase algorithm: any case that every individual passes provides no selective pressure.

Complexity Can we analytically calculate the probability of selection an individual with less complexity than executing the lexicase selection algorithm? It appears not. Eqn. 3 has a worst-case complexity of  $O(T^N)$  when all individuals are elite on  $\mathcal{T}$ , which discourages its use as a selection method. The lexicase selection algorithm samples the expected probabilities of each individual by recursing on random orders of cases in  $\mathcal{T}$ , considering one at a time rather than branching to consider all combinations of cases that could result in selection for each individual in question. This gives lexicase selection a complexity of O(TN) for selecting a single parent, and therefore a complexity of  $O(TN^2)$  per generation.

### 5.1 Effect of N and T

What does the an analysis of the probability of selection for lexicase selection tell us about how lexicase behaves for cases in which  $|\mathcal{N}| << |\mathcal{T}|$ ?  $|\mathcal{T}| << |\mathcal{N}|$ ?

The sampling of  $P_{sel}$  done by lexicase is tied to the population size because lexicase selection conducts N depth-first searches of the case orderings to choose N parents. This implies that the value of N determines the fidelity with which  $P_{sel}$  is approximated via the sampling. Smaller populations will therefore produce poorer approximations of  $P_{sel}$ .

The effectiveness of lexicase selection has also been tied to the number of fitness cases, T. When T is small, there are very few ways in which individuals can be selected. For example, if T = 2, an individual

must be elite on one of these two cases to be selected. For continuous errors in which few individuals are elite, this means that only two individuals are likely to produce all of the children for the subsequent generation.

## 5.2 Effect of different population structures

- 1. compare probability of lexicase selection to probability of selection with tournament / roulette
- 2. compare population structures: maintain correlation structure and vary population size/ number of test cases
- 3. see how many iterations of lexicase selection are required to converge on the probabilities of selection for the example problem in Table 1
- 4. population where there is one individual that sucks at everything but is good at other things how does it compare to tournament selection probabilities?
- 5. do not assume that N rounds of lexicase selection are conducted!

**Probabilities under tournament selection** We compare the probability of selection under lexicase selection to that using tournament selection with an indentical population and fitness structure. To do so we must first formulate the probability of selection for an individual undergoing tournament selection with r-size tournaments. Consider that the mean absolute error is used to aggregate the fitness cases. Then the fitness ranks of  $\mathcal{N}$  can be calculated, with lower rank indicating better fitness. Let  $S_i$  be the individuals in  $\mathcal{N}$  with a fitness rank of i, and let Q be the number of unique fitness ranks. Then Xie et. al. [17] showed that the probability of selecting an individual with rank j in a single tournament is

$$P_{t} = \frac{1}{|S_{j}|} \left( \left( \frac{\sum_{i=j}^{Q} |S_{i}|}{N} \right)^{r} - \left( \frac{\sum_{i=j+1}^{Q} |S_{i}|}{N} \right)^{r} \right)$$
(4)

In Table 1, the selection probabilities for the example population are shown according to tournament selection.

# 6 Multi-objective Interpretation of Lexicase Selection

Objectives and training cases are fundamentally different entities: objectives define the goals of the task being learned, whereas cases are the units by which progress towards those objectives is measured. By this criteria, lexicase selection and multi-objective optimization have historically been differentiated [4], although there is clearly a "multi-objective" interpretation of the behavior of lexicase selection with respect to the training cases. If we assume for a moment that we treat individual fitness cases as objectives to solve, we can consider most learning tasks to be high-dimensional many-objective optimization problems. At this scale, the most popular multi-objective methods (e.g. NSGA-II and SPEA-2) tend to perform poorly, a behavior that has been explained in literature [16, 3]. Farina and Amato [3] point out two short-comings of these multi-objective methods when many objectives are considered:

the Pareto definition of optimality in a multi-criteria decision making problem can be unsatisfactory due to essentially two reasons: the number of improved or equal objective values is not taken into account, the (normalized) size of improvements is not taken into account

Lexicase selection is guarantees the return of individuals that are on the Pareto front with respect to the fitness cases. This is a necessary but not sufficient condition. In fact, lexicase selection only selects those individuals in the "corners" of the Pareto front, meaning they are on the front and elite, globally, with respect to at least one fitness case. Put another way, no individual can be selected via lexicase selection unless it is elite with respect to at least one objective among the entire population, regardless of its performance on other objectives.

Interestingly, the worst-case complexity of NSGA-II is the best-case complexity for lexicase selection. Add notes from discourse

Here we define Pareto dominance relations with respect to the training cases.

**Definition 1:**  $n_1$  dominates  $n_2$ , i.e.,  $n_1 \prec n_2$ , if  $e_j(n_1) \leq e_j(n_2) \ \forall j \in \{1, \dots, T\}$  and  $\exists j \in \{1, \dots, T\}$  for which  $e_j(n_1) < e_j(n_2)$ .

**Definition 2:** The *Pareto set* of  $\mathcal{N}$  is the subset of  $\mathcal{N}$  that is non-dominated with respect to  $\mathcal{N}$ ; i.e.,  $n \in \mathcal{N}$  is in the Pareto set if  $n \not\prec m \ \forall \ m \in \mathcal{N}$ .

**Definition 3:**  $n \in \mathcal{N}$  is a *Pareto set boundary* if n is in the Pareto set of  $\mathcal{N}$  and  $\exists j \in \{1, ..., T\}$  for which  $e_j(n_1) \leq e_j(m) \ \forall \ m \in \mathcal{N}$ .

With these definitions in mind, we show that individuals selected by lexicase are on the Pareto set boundaries.

**Theorem 1:** If individuals from a population  $\mathcal{N}$  are selected by lexicase selection, those individuals are Pareto set boundaries of  $\mathcal{N}$  with respect to  $\mathcal{T}$ .

**Proof:** First, we prove (by supposing a contradiction) that individuals selected by lexicase are in the Pareto set. Second, we prove these individuals to be Pareto set boundaries.

First: Let  $n_1, n_2 \in \mathcal{N}$  be individuals in a population selected by lexicase selection. Suppose  $n_1 \prec n_2$ . Then  $e_j(n_1) \leq e_j(n_2) \ \forall j \in \{1, \dots, N\}$  and  $\exists j \in \{1, \dots, T\}$  for which  $e_j(n_1) < e_j(n_2)$ . Therefore  $n_1$  is selected for every case that  $n_2$  is selected, and  $\exists t \in \mathcal{T}$  for which  $n_2$  is removed from selection due to  $n_1$ . Hence,  $n_2$  cannot be selected by lexicase selection and the supposition is false. Therefore  $n_1$  and  $n_2$  must be in the Pareto set.

Second: let n be an individual selected from population  $\mathcal{N}$  by lexicase selection. Then by definition of the Algorithm 1,  $\exists j \in \{1, \ldots, T\}$  for which  $e_j(n) \leq e_j(m) \ \forall \ m \in \mathcal{N}$ . Therefore, since n is in the Pareto set of  $\mathcal{N}$  and according to Definition 3, n is a Pareto set boundary of  $\mathcal{N}$ .

Extension to  $\epsilon$ -lexicase selection We can extend our multi-objective analysis to  $\epsilon$ -lexicase selection for conditions in which  $\epsilon$  is pre-defined for each fitness case, i.e. in static and dynamic cases, but not when  $\epsilon$  is recalculated for each selection pool. We first define  $\epsilon$  elitism in terms of a relaxed dominance relation and a relaxed Pareto set. We define the dominance relation with respect to  $\epsilon$  as follows:

**Definition 4:**  $n_1 \epsilon$ -dominates  $n_2$ , i.e.,  $n_1 \prec_{\epsilon} n_2$ , if  $e_j(n_1) + \epsilon_j \leq e_j(n_2) \ \forall j \in \{1, \ldots, T\}$  and  $\exists j \in \{1, \ldots, T\}$  for which  $e_j(n_1) + \epsilon_j < e_j(n_2)$ , where  $\epsilon_j > 0$  is defined according to Eqn. 2

It is important to note that this definition of  $\epsilon$ -dominance differs from a previous  $\epsilon$ -dominance definition used by Laumanns et. al. [11] (cf. Eqn. (6)) in which  $n_1 \prec_{\epsilon} n_2$  if

$$e_j(n_1) + \epsilon_j \le e_j(n_2) \ \forall \ j \in \{1, \dots, T\}$$

According to Definition 4, the  $\epsilon$ -dominance criteria is more strict, requiring  $e_j(n_1) + \epsilon_j < e_j(n_2)$  for at least one j. As a result, the non- $\epsilon$ -dominated set, defined as the  $\epsilon$ -Pareto set below, is expected to be as large or larger than the  $\epsilon$ -approximate Pareto set used in [11].

**Definition 5:** The  $\epsilon$ -Pareto set of  $\mathcal{N}$  is the subset of  $\mathcal{N}$  that is non- $\epsilon$ -dominated with respect to  $\mathcal{N}$ ; i.e.,  $n \in \mathcal{N}$  is in the Pareto set if  $n \not\prec_{\epsilon} m \ \forall \ m \in \mathcal{N}$ .

**Definition 6:**  $n \in \mathcal{N}$  is an  $\epsilon$ -Pareto set boundary if n is in the  $\epsilon$ -Pareto set of  $\mathcal{N}$  and  $\exists j \in \{1, \ldots, T\}$  for which  $e_j(n_1) \leq e_j(m) + \epsilon_j \ \forall \ m \in \mathcal{N}$ , where  $\epsilon_j$  is defined according to Eqn 2.

**Theorem 2:** If  $\epsilon$  is defined according to Eqn. 2, and if individuals are selected from a population  $\mathcal{N}$  by  $\epsilon$ -lexicase selection, then those individuals are elements are  $\epsilon$ -Pareto set boundaries of  $\mathcal{N}$ .

**Proof:** First: Let  $n_1$  and  $n_2$  be individuals selected from  $\mathcal{N}$  by static or semi-dynamic  $\epsilon$ -lexicase selection. Suppose  $n_1 \prec_{\epsilon} n_2$ . Then  $n_1$  is selected for every case that  $n_2$  is selected, and  $\exists t \in \mathcal{T}$  in every selection event for which  $n_2$  is removed from selection due to  $n_1$ . Hence,  $n_2$  cannot be selected by lexicase selection and the supposition  $n_1 \prec_{\epsilon} n_2$  is false. Therefore  $n_1$  and  $n_2$  must be in the  $\epsilon$ -Pareto set of  $\mathcal{N}$  to be selected.

Second: let n be an individual selected from population  $\mathcal{N}$  by static or semi-dynamic  $\epsilon$ -lexicase selection. Then by definition of Algorithm 2 or 3,  $\exists j \in \{1, \ldots, T\}$  for which  $e_j(n) \leq e_j(m) \ \forall \ m \in \mathcal{N}$ . Since n is in the  $\epsilon$ -Pareto set of  $\mathcal{N}$  and according to Definition 3, n must be a  $\epsilon$ -Pareto set boundary of  $\mathcal{N}$ .

The notion of the selection of Pareto set boundaries by lexicase selection is illustrated in Figure 2 for a scenario with two fitness cases. Each point in the plot represents an individual, and the squares are the Pareto set. Under a lexicase selection event with case sequence  $\{t_1, t_2\}$ , individuals would first be filtered to the two left-most individuals that are elite on  $e_1$ , and then to the individual among those two that is best on  $e_2$ , i.e. the selected square individual. Note that the selected individual is a Pareto set boundary. Given the opposite order of cases, i.e.  $\{t_2, t_1\}$ , the individual on the other end of the Pareto set (the other boundary) would be selected.

Consider the analogous case for semi-dynamic  $\epsilon$ -lexicase selection illustrated in Figure 3. In this case the Pareto set is indicated again by squares. Under a semi-dynamic  $\epsilon$ -lexicase selection event with case order  $\{t_1, t_2\}$ , the population would first be filtered to the 4 left-most individuals that are within  $\epsilon_1$  of the elite error on case  $t_1$ , and then the indicated square would be selected by being the only individual within  $\epsilon_2$  of the elite error on  $t_2$  among the current pool. It is important to note that that although the selected individual is an  $\epsilon$ -Pareto set boundary by Definition 6, it is *not* a boundary of the Pareto set. Theorem 2 only guarantees that the selected program is within  $\epsilon$  of the best error for at least one case, which in this scenario is  $t_1$ .

Comparing Figures 2 and 3 illustrates the effect of introducing  $\epsilon$  to the filter conditions in lexicase: it reduces the selectivity of each case, ultimately resulting in the selection of individuals that are not as extremely positioned in semantic space. Regarding the position of solutions in this space, it's worth noting the significance of boundary solutions (and near boundary solutions) in the context of multi-objective optimization. Boundary solutions are known to contribute significantly to hypervolume measures [2], where the hypervolume is a measure of how well-covered the objective space is by the current set of solutions. The boundary solutions have an infinite score according to NSGA-II's crowding measure [1], with higher being better, meaning they are the first non-dominated solutions to be preserved by selection when the population size is reduced. Nonetheless, multi-objective literature appears divided on how these boundary solutions drive search [16], when the goal of the algorithm is to approximate the optimal Pareto front. In contrast, the goal of GP is to preserve points in the search space that, when combined and varied, yield a single best solution. So while the descriptions above lend insight to the function of lexicase and  $\epsilon$ -lexicase selection, it's important to remember the different goals of search and the high dimensionality of training cases when compared to objectives.

# 7 Illustrative Example

**Example** As an example of calculating absolute probabilities, we consider the illustrative problem from the original lexicase selection paper [?], shown in Table 1. Using Eqn. 3, the probabilities for each individual can be calculated as follows:

$$P_{sel}(n_1) = 1/4 * (1/3 * (1) + 1/3 * (1 + 1)) = 0.25$$

$$P_{sel}(n_2) = 1/4 * (0) = 0$$

$$P_{sel}(n_3) = 1/4 * (1/3 * (1 + 1/2 * (1)) + 1/3 * (1)) = 0.20833$$

$$P_{sel}(n_4) = 1/4 * (1/3 * (1/2 * (1) + 1) + 1/3 * (1)) = 0.20833$$

# Lexicase Selection sequence: $\{t_1, t_2\}$

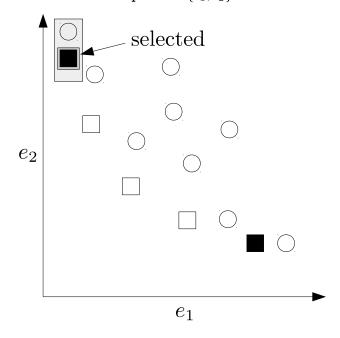

Figure 2: An illustration of the performance of lexicase selection in a scenario involving two cases. Each point represents and individual in the population. The squares are individuals in the Pareto set. A selection event for case sequence  $\{t_1, t_2\}$  is shown by the gray rectangles. The black points are individuals that could be selected by any case ordering.

Table 1: Example population from original lexicase paper (Spector 2013).

Program	Test				$\mathcal{K}(\mathcal{T})$	MAE	$P_{sel}$	$P_t$
	$t_1$	$t_2$	$t_3$	$t_4$				
$n_1$	2	2	4	2	$\{t_2, t_4\}$	2.5	0.25	0.28
$n_2$	1	2	4	3	$\{t_2\}$	2.5	0.00	0.28
$n_3$	2	2	3	4	$\{t_2, t_3\}$	2.75	0.33	0.12
$n_4$	0	2	5	5	$\{t_1, t_2\}$	3.0	0.208	0.04
$n_5$	0	3	5	2	$\{t_1, t_4\}$	2.5	0.208	0.28

# $\epsilon$ -Lexicase Selection sequence : $\{t_1, t_2\}$

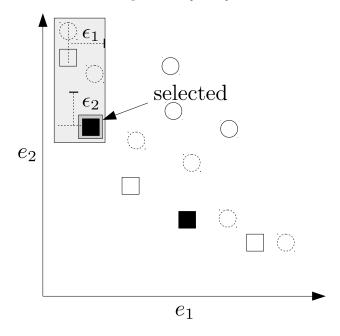

Figure 3: An illustration of the performance of semi-dynamic  $\epsilon$ -lexicase selection in a scenario involving two cases. Each point represents and individual in the population. The squares are individuals in the Pareto set, and the circles with dotted lines are the subset of Pareto set individuals that are also in the  $\epsilon$ -Pareto set. A selection event for case sequence  $\{t_1, t_2\}$  is shown by the gray rectangles. The black points are individuals that could be selected by any case ordering.

Table 2: Example population with test case performances and selection probabilities according to the different algorithms.

$\mathcal{N}$			Cases			Mean		Probabi	lity of S	election

$n_8$	2.1	0.2	1.0	7.0	1.0	2.26	0.111	0.000	0.133	0.133	0.217
$n_9$	2.2	0.0	1.1	8.0	0.0	2.26	0.111	0.400	0.133	0.133	0.050
$\epsilon$	0.9	0.9	0.9	2.0	2.0						

Illlustrative Example 2 A more complex population semantic structure is presented in Table 2 featuring floating point errors. In this case, the population semantics are completely unique, although they result in the same mean error across the training cases, as shown in the "Mean" column. As a result, tournament selection picks uniformly from among these individuals.

As mentioned earlier, with unique populations, lexicase selection is proportional to the number of cases for which an individual is elite. This leads lexicase selection to pick from among the 4 individuals that are elite on cases, i.e.  $n_1$  ( $t_1$ ),  $n_4$  ( $t_4$ ),  $n_5$  ( $t_3$ ), and  $n_9$  ( $t_2,t_5$ ), with respective probabilities 0.2, 0.2, 0.2, and 0.4.

Due to its strict definition of elitism, lexicase selection does not account for the fact other individuals are very close to being elite on these cases as well. The  $\epsilon$ -lexicase variants address this as noted by the smoother distribution of selection probabilities among this population. Focusing first on static  $\epsilon$ -lexicase selection, it is worth illustrating the pass conditions for the population by applying the  $\epsilon$  threshold, yielding the following errors:

	$t_1$	$t_2$	$t_3$	$t_4$	$t_5$
$n_1$	0	1	1	1	1
$n_2$	0	1	1	0	1
$n_3$	0	1	1	0	1
$n_4$	1	1	0	0	1
$n_5$	1	1	0	1	1
$n_6$	1	1	0	1	1
$n_7$	1	0	1	1	0
$n_8$	1	0	1	1	0
$n_9$	1	0	1	1	0

The selection probabilities for static  $\epsilon$  lexicase selection are equivalent to the selection probabilities of lexicase selection on this converted semantic matrix. Despite elitism on case  $t_1$ ,  $n_1$  is not selected since  $n_2$  and  $n_3$  are  $\epsilon$ -elite on this case as well as  $t_4$ . Consider  $n_4$ , which has a higher probability of selection under static  $\epsilon$ -lex than lexicase selection. This is due to it being  $\epsilon$ -elite on a unique combination of cases:  $t_3$  and  $t_4$ . Lastly  $n_8$  is selected in equal proportions to  $n_7$  and  $n_6$  since all are within  $\epsilon$  of the elite error on the same cases.

Semi-dynamic  $\epsilon$  lexicase selection allows for all 9 individuals to be selected with varying proportions that are similar to those derived for static  $\epsilon$  lexicase selection. Selection probabilities for  $n_1$  illustrate the differences in the static and semi-dynamic variants:  $n_1$  has a chance for selection in the semi-dynamic case because when  $t_1$  is selected as the first case,  $n_1$  is within  $\epsilon$  of the best case errors among the pool, i.e.  $\{n_1, n_2, n_3\}$ , for any subsequent order of cases. The probability of selection for  $n_5$  and  $n_6$  follow the same pattern.

Dynamic  $\epsilon$ -lexicase selection produces the most differentiated selection pressure for this example. Consider individual  $n_8$  which is the most likely to be selected for this example. It is selected more often than  $n_7$  or  $n_9$  due to the adaptations to  $\epsilon$  as the selection pool is winnowed. For example,  $n_8$  is selected by case sequence  $\{t_2, t_1, t_3\}$ , for which the selection pool takes the following form after each case:  $\{n_7, n_8, n_9\}, \{n_7, n_8\}, \{n_8\}$ . Under the other semi-dynamic  $\epsilon$  lexicase selection,  $n_7$  and  $n_8$  would not be removed by these cases due to the fixed nature of  $\epsilon$  for those cases. The probabilities of selection for the population in Table 2 is shown graphically in Figure 7.
